Abstract—Unique word - orthogonal frequency division multiplexing (UW-OFDM) is a novel OFDM concept that uses deterministic sequences, which we call unique words, as guard intervals instead of the conventional cyclic prefixes. Since unique words represent known sequences, they can advantageously be used for synchronization, channel estimation, but also for improving the bit error ratio (BER) behavior of a system. These UWs are created by appropriately loading so-called redundant subcarriers. In this paper, we investigate methods to improve the BER behavior of UW-OFDM by increasing the number of redundant subcarriers (while keeping the length of the UW constant). This gain in the BER performance comes with an increase of the redundancy part and thus with a decrease of the data rate. As such, we present methods to vary the coding rate in UW-OFDM. We present results for the additive white Gaussian noise (AWGN) channel as well as for indoor multipath environments to highlight the advantages of the proposed methods.

I. INTRODUCTION

In mobile communications, multipath propagation is a crucial phenomenon which we have to cope with. Mobile radio channels in indoor or cellular environments can exhibit relatively large time dispersions, i.e. intersymbol interference (ISI). In orthogonal frequency division multiplexing (OFDM) systems, ISI can easily be eliminated by introducing a guard interval between two consecutive OFDM symbols. Furthermore, implementing these guard intervals as cyclic prefixes (CPs) [1] transforms the linear convolution of the transmit signal with the channel impulse response into a cyclic convolution, allowing for a low complexity equalization in the frequency domain. The same can also be achieved by using unique words (UWs) instead of CPs. Nevertheless, there are some fundamental differences between the CP-based and UW-based transmission:

- The UW is part of the discrete Fourier transform (DFT) interval, whereas the CP is not (cf. Fig. 1).

The CP is random, whereas the UW is a known deterministic sequence, which can advantageously be used for synchronization [2] and channel estimation [3] purposes.

- The implementation of a UW in the time domain introduces correlations in the frequency domain. These correlations can be exploited to improve the bit error ratio (BER) behavior of the system [4].

Fig. 1. Transmit data structure using CPs (above) or UWs (below).

First ideas of how to use UWs in OFDM have already been proposed in [5] where the concept is called DMT-KSP (discrete multi-tone - known symbol padding). The paper provides a theoretical concept of how to create an OFDM symbol featuring a UW at its tail, but the approach fails to compete with the performance of UW-OFDM systems, or as named in the paper, SC-KSP (single carrier - known symbol padding) systems. The authors notice that the performance of DMT-KSP is highly sensitive to the choice of the UW. Our approach of how to create UW-OFDM symbols described in [4] differs from the concept in [5] in two ways: Different as in [5] we optimize the positions of the so-called redundant subcarriers (details are described below) in frequency domain, and most importantly, we use a different method to generate the UWs which we call two-step approach. In fact, we showed in [6] that the two-step approach significantly outperforms the approach in [5] (which we call single-step determination of the UW in [4] and [6]). We note that the two-step approach produces completely different OFDM symbols than the single-step approach. The only thing they have in common is the UW-tail. Furthermore, in contrast to the single-step method, the choice of the UW has no influence on the data estimation performance in the two-step approach.

In [7], the term UW-OFDM is not used, but the presented concept is closely related to what we call UW-OFDM. There,
the approach is considered from a coding theory perspective. The authors propose to use a zero word within OFDM time-domain symbols. The concatenated zero samples in time domain in combination with unused subcarriers forming guard bands in the frequency domain are interpreted as a time-frequency Reed-Solomon code with a Hamming distance in time and frequency domain. The authors notice, that consecutively used redundancy and consecutive error pattern in the other domain leads to an ill-conditioned problem which does not allow to determine the errors even if the error positions are known. The authors mention that they will concentrate further work on improving the stability, i.e. lowering the condition number of the underlying system of equations.

Several other attempts of applying UWs in OFDM systems can be found in the literature, e.g. in [8], [9], [10] and [11]. Although they are called differently like KSP-OFDM, time-domain synchronous OFDM (TDS-OFDM) or pseudorandom postfix OFDM (PRP-OFDM), and may sometimes also differ in the specific design of the UW, all approaches share one common property making them completely different from [5] and also from our approach: In all cases, the guard interval and thus the UW is not part of the DFT interval. Therefore, different to our UW-OFDM approach described below, no correlations along the subcarriers and thus no coding gain is introduced by these concepts.

We have shown in [4] how to create UWs by appropriately loading so-called redundant subcarriers. By this, correlations along the frequency domain vector of an OFDM symbol are introduced. Investigations in [4] have unveiled that the energy spent for the redundant subcarriers is critical. In this paper, we extend the results of [4] by increasing the number of redundant subcarriers (while keeping the same length for the UW). By this, the total energy on the redundant subcarriers is reduced and thus the BER performance improved. However, this gain in the BER behavior leads to a decrease of the data rate. As such, the presented ideas can be seen as methods to vary the coding rate in UW-OFDM. In the following, we will refer to this coding rate as “inner coding rate”.

The rest of the paper is organized as follows: In section II, we describe our approach of how to introduce unique words in OFDM symbols. Furthermore, we present methods to decrease the energy of the redundant subcarrier symbols by changing the inner coding rate of the system. Section III introduces a linear minimum mean square error (LMMSE) receiver that exploits the correlations introduced by the redundant subcarriers. Section IV evaluates the impact of the energy of the redundant subcarrier symbols on the BER behavior by means of simulations, and section V concludes our work.

Notation Lower-case bold face variables (a, b, ...) indicate vectors, and upper-case bold face variables (A, B, ...) indicate matrices. To distinguish between time and frequency domain variables, we use a tilde to express frequency domain vectors and matrices (\(\tilde{a}, \tilde{A}, \ldots\)), respectively. We further use \(\mathbb{C}\) to denote the set of complex numbers, \(\mathbb{I}\) to denote the identity matrix, \((\cdot)^T\) to denote transposition, \((\cdot)^H\) to denote conjugate transposition, \((\cdot)^\dagger\) to denote the Pseudo-Inverse, and \(E(\cdot)\) to denote expectation.

II. Unique Word Generation for OFDM

In conventional CP-OFDM, the data vector \(\bar{d} \in \mathbb{C}^{N_d \times 1}\) is defined in the frequency domain. Typically, zero subcarriers are inserted at the band edges and at the DC subcarrier position, which can formally be described by a matrix operation \(\bar{x} = \mathbf{B}\bar{d}\) with \(\bar{x} \in \mathbb{C}^{N \times 1}\) and \(\mathbf{B} \in \mathbb{C}^{N \times N_d}\). \(\mathbf{B}\) consists of zero-rows at the positions of the zero subcarriers, and of appropriate unit row vectors at the positions of data subcarriers. The vector \(\bar{x}\) denotes the OFDM symbol in frequency domain. The vector of time domain samples \(x \in \mathbb{C}^{N \times 1}\) is calculated via an IDFT (inverse DFT) operation, which can conveniently be formulated in matrix notation by \(x = \mathbf{F}_N^{-1}\tilde{x}\). Here, \(\mathbf{F}_N\) is the \(N\)-point DFT matrix defined by \(\mathbf{F}_N = (f_{mn})\) with \(f_{mn} = \frac{1}{\sqrt{N}}e^{-j2\pi mn/N}\) for \(m = 0, 1, ..., N - 1\), \(n = 0, 1, ..., N - 1\), and with \(w = e^{-j2\pi/N}\).

We now modify this conventional approach by introducing a pre-defined sequence \(x_u\) with \(x_u \in \mathbb{C}^{N_u \times 1}\), which we call unique word, and which shall form the tail of the time domain vector, which we now denote by \(x'\). Hence, \(x'\) consists of two parts and is given by \(x' = [x_0^T \ x_u^T]^T\), where \(x_0 \in \mathbb{C}^{(N-N_u) \times 1}\) and \(x_u \in \mathbb{C}^{N_u \times 1}\). The vector \(x_u\) represents the UW of length \(N_u\), and thus only \(x_u\) is random and affected by the data. We use a two step approach [6] to generate the so-defined vector \(x'\):

- In a first step, we will generate a zero UW \(x = [x_0^T \ 0^T]^T\), such that \(x = \mathbf{F}_N^{-1}\tilde{x}\).
- In a second step, we will determine the transmit symbol by \(x' = x + [0^T \ x_u^T]^T\).

We now describe the first step in detail: As in conventional OFDM, the QAM data symbols and the zero subcarriers are specified in the frequency domain in vector \(\tilde{x}\), but here in addition, the zero word is specified in the time domain as part of the vector \(x\). As a consequence, the linear system of equations \(x = \mathbf{F}_N^{-1}\tilde{x}\) can only be fulfilled by reducing the number \(N_d\) of data subcarriers, and by introducing a set of redundant subcarriers instead. We let the redundant subcarriers form the vector \(\tilde{r} \in \mathbb{C}^{N_r \times 1}\), requiring \(N_r \geq N_u\). Additionally, we redefine the dimensions of \(\mathbf{B}\) such that \(\mathbf{B} \in \mathbb{C}^{N \times (N_d+N_u)}\), further introduce a permutation matrix \(\mathbf{P} \in \mathbb{C}^{(N_d+N_r) \times (N_d+N_u)}\), and form an OFDM symbol containing \(N-N_d-N_r\) zero subcarriers in frequency domain by \(\bar{x} = \mathbf{BP} [\bar{d}^T \ \tilde{r}^T]^T\). We will detail the reason for the introduction of the permutation matrix and its specific construction shortly below. Fig. 2 illustrates this approach in a graphical way: The input of the IDFT block is composed of data subcarrier symbols (\(\bar{d}\)), zero subcarriers, and redundant subcarrier symbols (\(\tilde{r}\)), which are distributed over the entire non-zero part of vector \(\tilde{x}\) as specified by the permutation matrix \(\mathbf{P}\). The output of the IDFT block, which corresponds to the vector \(x\) of time domain samples of an OFDM symbol, is composed of the random part \(x_u\), and the zero UW \(0\).

The relation between the time and the frequency domain
representation of an OFDM symbol can now be written as
\[ F_N^{-1}BP \begin{bmatrix} \tilde{d} \\ \tilde{r} \end{bmatrix} = \begin{bmatrix} x_d \\ 0 \end{bmatrix}, \] (1)

With
\[ M = F_N^{-1}BP = \begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix}, \] (2)

where \( M_{ij} \) are appropriately sized sub-matrices, it follows that \( M_{21}\tilde{d} + M_{22}\tilde{r} = 0 \). In the following, we will distinguish between two different cases, namely \( N_r = N_u \) and \( N_r > N_u \).

In case of \( N_r = N_u \), the problem to be solved translates to a linear system of equations with \( N_u \) equations for \( N_u \) unknowns and thus is uniquely solvable. More in detail, \( M_{22} \) becomes a quadratic matrix of dimension \( N_u \times N_u \) with a uniquely defined inverse, leading to \( \tilde{r} = -M_{22}^{-1}M_{21}\tilde{d} \). With the matrix \( T = -M_{22}^{-1}M_{21}(T \in \mathbb{C}^{N_r \times N_u}) \), the vector of redundant subcarrier symbols can thus be determined by the linear mapping
\[ \tilde{r} = T\tilde{d}. \] (3)

It is clear now how to load \( \tilde{r} \) in order to create the desired zero word as UW. However, as we have already mentioned that the energy present on the redundant subcarriers is critical, we additionally wish to minimize this energy. In case of \( N_r = N_u \), the choice of the permutation matrix is the only degree of freedom to achieve this. The permutation matrix \( P \) determines the positions of the redundant subcarriers \( \tilde{r} \) within \( \tilde{x} \). Since changing the positions based on the current data \( \tilde{d} \) and therefore during transmission seems impracticable, we thus would like to find a \( P \) such that the energy of \( \tilde{r} \) is minimized over all possible data vectors on average, i.e., minimizing \( E(\tilde{r}^H\tilde{r}) \). Assuming i.i.d. zero-mean data QAM symbols with variance \( \sigma_d^2 \) and taking into account (3), this leads to the following optimization problem:
\[ P = \arg \min \{ \text{tr}(TT^H) \}. \] (4)

It turns out that the right choice of \( P \) is very critical with respect to the resulting energy on \( \tilde{r} \). Experiments show that an approximately equidistant distribution of the redundant subcarriers provides low energy, whereas bundles of them result in extremely high energy values. In section IV, we will present some optimal distributions for different values of \( N_r \) obtained from heuristic optimization methods.

In case of \( N_r > N_u \), the problem to be solved translates to an underdetermined linear system of equations and thus provides infinitely many solutions. Besides the choice of the permutation matrix \( P \), we have now an additional degree of freedom to minimize the energy on the redundant subcarriers, leading to the following optimization criterion:
\[ \min \| \tilde{r} \|_2 \text{ s.t. } M_{21}\tilde{d} + M_{22}\tilde{r} = 0. \] (5)

Here, \( \| \cdot \|_2 \) denotes the Euclidean norm defined as \( \| \tilde{r} \|_2 = \sqrt{\tilde{r}^H\tilde{r}} \). Note that in contrast to (4), we aim at finding the optimum for each individual transmit symbol instead of just finding the optimum on average. This means that we take into account the actual data subcarrier symbols \( \tilde{d} \) instead of their statistical properties. Eq. (5) is met with optimality by the Pseudo-Inverse defined as \( M_{22}^{-1} = (M_{22}^HM_{22})^{-1}M_{22}^H \) (\( M_{22}^H \in \mathbb{C}^{N_r \times N_u} \)), leading to \( \tilde{r} = -M_{22}^{-1}M_{21}\tilde{d} \). With \( T = -M_{22}^{-1}M_{21}(T \in \mathbb{C}^{N_r \times N_u}) \) we arrive at the linear mapping as in (3).

For both cases, i.e. independent of \( N_r = N_u \) or \( N_r > N_u \), we can now use the notation \( \tilde{s} \) with
\[ \tilde{s} = P \begin{bmatrix} \tilde{d} \\ \tilde{r} \end{bmatrix} = P \begin{bmatrix} 1 \\ T \end{bmatrix} \tilde{d} = G\tilde{d}. \] (6)

\( \tilde{s} \in \mathbb{C}^{(N_d+N_r) \times 1} \), \( G \in \mathbb{C}^{(N_d+N_r) \times N_d} \) for the non-zero part of \( \tilde{x} \), such that \( \tilde{x} = BS \). Finally, the transmit symbol \( x' \) is generated by adding the unique word like described earlier. The frequency domain representation \( \tilde{x}_u' \in \mathbb{C}^{N_x \times 1} \) of the UW is defined by \( \tilde{x}_u' = F_N^H \begin{bmatrix} 0^T \\ x_u^T \end{bmatrix} \). Note that \( x' \) can also be written as \( x' = F_N^{-1}(\tilde{x}_u' + \tilde{x}) = F_N^{-1}(\tilde{x}_u' + BS) \). The mean energy \( E_{x'} \) of the transmit symbol \( x' \) can be shown to be
\[ E_{x'} = \frac{1}{N} \left( N_d\sigma_d^2 + \sigma_e^2\text{tr}(TT^H) \right) + x_u^H\tilde{x}_u. \] (7)

\( E_d \) and \( E_{x_u} \) describe the contributions of the data and the redundant subcarrier symbols to the total mean symbol energy before the addition of the UW, respectively, and \( E_{x_u} \) describes the contribution of the UW. We will refer back to this equation more in detail in section IV.

III. OFDM RECEIVER

Let \( x' \) be the transmit symbol, then after the transmission over a multipath channel and after the common DFT operation (preferably implemented as FFT (fast Fourier transform)), the non-zero part \( y \in \mathbb{C}^{(N_d+N_r) \times 1} \) of a received OFDM frequency domain symbol can be modeled as \( y = F_N^H\tilde{x}_u' + B\tilde{s} + F_Nn \), where \( H \) denotes a cyclic convolution matrix with \( H \in \mathbb{C}^{N \times N} \), and \( n \in \mathbb{C}^{N \times 1} \) represents a noise vector with the covariance matrix \( \sigma_n^2I \). The multiplication with \( B^H \) excludes the zero subcarriers from further operation. The matrix \( F_N^H\tilde{x}_u' \) is diagonal and contains the sampled channel frequency response on its main diagonal. \( \tilde{H} = B^HF_N^H\tilde{x}_u'B \) with \( \tilde{H} \in \mathbb{C}^{(N_d+N_r) \times (N_d+N_r)} \) is a down-sized version of \( F_N^H\tilde{x}_u'B \) excluding the entries corresponding to the zero subcarriers. The received symbol can therefore also be formulated...
as
\[
\hat{y} = \hat{H}(B^T\hat{x}'_u + \tilde{s}) + B^T F_N n.
\]
(8)

One can show that the LMMSE [12] receiver can be written as
\[
\hat{d} = \hat{W}\hat{H}^{-1}(\tilde{y} - \hat{H}\hat{B}^T\hat{x}'_u),
\]
(9)

whereas the Wiener smoothing matrix \(\hat{W}\) is given by
\[
\hat{W} = G^H \left(GG^H + \frac{N\sigma_n^2}{\sigma_d^2} (\hat{H}^H\hat{H})^{-1}\right)^{-1}. 
\]
(10)

Note that the error \(\tilde{e} = \hat{d} - \hat{\tilde{d}}\) has zero mean, and its covariance matrix is given by \([12]\) \(C_{\tilde{e}\tilde{e}} = \sigma_d^2 \left(1 - \tilde{W}G\right)\), which can be further utilized when channel coding is applied. Furthermore, we notice from (9) that we first subtract \(\hat{H}\hat{B}^T\hat{x}'_u\) from \(\tilde{y}\) before applying equalization. As such, the specific choice of the UW does not influence the performance of the LMMSE receiver and can thus be chosen independently from that.

IV. Performance

This section will demonstrate how the inner coding rate and thus the energy present on the redundant subcarriers influences the performance of the UW-OFDM system in terms of the BER behavior. We will present results for the additive white Gaussian noise (AWGN) case and additionally for two dedicated multipath channel snapshots. Fig. 3 shows the block diagram of the simulated UW-OFDM system. Starting with channel coding, interleaving and mapping, the redundant subcarriers are loaded like indicated in (3). The OFDM symbol in the frequency domain is created by appropriately assembling \(\hat{d}\), \(\hat{r}\) and a set of zero subcarriers. Afterwards, an inverse fast Fourier transform (IFFT) is applied, and finally the UW is added in the time domain. At the receiver, we apply a FFT operation followed by a zero forcing (ZF) equalization. Next, the frequency domain representation of the UW is subtracted and a Wiener smoothing operation is applied. Finally, demapping, deinterleaving and decoding are performed. For the decoding step, we use a soft decision Viterbi approach with the main diagonal of the matrix \(C_{\tilde{e}\tilde{e}}\) as an additional input specifying the noise variances along the subcarriers after equalization and Wiener filtering.

We compare our novel UW-OFDM approach with the classical CP-OFDM concept. The IEEE 802.11a WLAN standard [13] serves as reference system. We apply the same parameters as in [13] wherever possible: \(N = 64\), sampling frequency \(f_s = 20\text{MHz}\), DFT period \(T_{DFT} = 3.2\mu\text{s}\), guard duration \(T_{GI} = 800\text{ns}\), and twelve zero subcarriers at the positions \(\{0, 27, 28, \ldots, 37\}\). Instead of \(N_d = 48\) data subcarriers and \(N_p = 4\) pilots, we use \(N_d\) data subcarriers and \(N_r\) redundant subcarriers, whereas \(28 < N_d < 36\) and \(16 < N_r < 24\), depending on the specific configuration. The data symbols are drawn from a QPSK alphabet with variance \(\sigma_d^2 = 1\), leading to a total mean energy of the data subcarrier symbols of \(E_x = \frac{N_d}{4}\). According to the guard duration, the UW has a length of \(N_u = 16\). In our approach, this UW shall take over the synchronization tasks which are normally performed with the help of the 4 pilot subcarriers. However, since in this paper, we only focus on the BER behavior of UW-OFDM, and since the performance of the proposed receiver is independent of the UW (see (9)), only the energy \(E_{x_u}\) of the UW but not the specific design is of interest in this case.

Table I compares our UW-OFDM approach with the IEEE 802.11a standard. The IEEE 802.11a WLAN standard [13] serves as reference system. We apply the same parameters as in [13] wherever possible: \(N = 64\), sampling frequency \(f_s = 20\text{MHz}\), DFT period \(T_{DFT} = 3.2\mu\text{s}\), guard duration \(T_{GI} = 800\text{ns}\), and twelve zero subcarriers at the positions \(\{0, 27, 28, \ldots, 37\}\). Instead of \(N_d = 48\) data subcarriers and \(N_p = 4\) pilots, we use \(N_d\) data subcarriers and \(N_r\) redundant subcarriers, whereas \(28 < N_d < 36\) and \(16 < N_r < 24\), depending on the specific configuration. The data symbols are drawn from a QPSK alphabet with variance \(\sigma_d^2 = 1\), leading to a total mean energy of the data subcarrier symbols of \(E_x = \frac{N_d}{4}\). According to the guard duration, the UW has a length of \(N_u = 16\). In our approach, this UW shall take over the synchronization tasks which are normally performed with the help of the 4 pilot subcarriers. However, since in this paper, we only focus on the BER behavior of UW-OFDM, and since the performance of the proposed receiver is independent of the UW (see (9)), only the energy \(E_{x_u}\) of the UW but not the specific design is of interest in this case.

Table I illustrates the subcarrier sets for various numbers of redundant subcarriers which have been used for evaluating the performance of the different UW-OFDM system configurations. These sets have been found by heuristic optimization methods subject to (4). As already mentioned earlier, the optimal sets with respect to achieving low energy on the redundant subcarriers turn out to follow a nearly equidistant distribution. Table II compares our UW-OFDM approach with the IEEE 802.11a system. We notice that our UW-OFDM approach needs about 0.4-0.5MHz less bandwidth \(B\) for transmission than the IEEE 802.11a system. These results have been obtained by simulations and measurements of the normalized power spectral density of the transmit bursts at -10dB down from the maximum of the flat region of the spectrum. The third row presents the bandwidth efficiency of the systems measured in megasymbols per seconds per MHz [Mbps/MHz] and is given by \(\eta = \frac{(N_d/T_{OFDM})}{B}\). The fourth row shows the bandwidth efficiency of the UW-
OFDM systems related to the IEEE 802.11a approach ($\eta_{rel}$). We notice that in case of $N_r = 16$, our UW-OFDM approach shows almost the same bandwidth efficiency as the conventional CP-OFDM approach. Increasing now $N_r$ leads of course to less bandwidth efficiency on one hand, but decreases the mean energy $\frac{E_b}{N_0}$ of the redundant subcarrier symbols and hence the mean energy per bit $E_b$ on the other hand. The AWGN loss is calculated as $10 \log_{10} \left( \frac{E_b}{N_0} \right)$, whereas $E_b = 0.01058$ determines the mean energy per bit for the IEEE 802.11a system and $E_{b,UW}$ that of the specific UW-OFDM system. It specifies the loss of UW-OFDM compared to IEEE 802.11a when just a simple zero forcing equalizer (without additional Wiener smoothing) is applied. As such, decreasing $E_b$ for UW-OFDM will decrease this loss. Fig. 4 confirms this effect by means of simulations. At a BER of $10^{-6}$, the UW-OFDM without smoothing loses around 2.05dB against the IEEE 802.11a standard in case of $N_r = 16$, 1.55dB for $N_r = 20$ and 1.3dB for $N_r = 24$, respectively. These results coincide with that of table II up to negligible simulation inaccuracies. However, the Wiener smoother exploits the correlations between the subcarriers of an OFDM symbol and improves the performance of the UW-OFDM system in the AWGN channel by around 1.5dB for all investigated modes, leading to a residual performance loss compared to the IEEE 802.11a standard of only 0.55dB for $N_r = 16$ and 0.05dB for $N_r = 20$, respectively. In case of $N_r = 24$, the UW-OFDM system even outperforms the IEEE 802.11a system by 0.2dB. We will show in the following that in case of frequency selective environments (at least for the selected scenarios), the UW-OFDM system always outperforms the IEEE 802.11a system regardless of $N_r$.

The multipath channel has been modeled as a tapped delay line, each tap with uniformly distributed phase and Rayleigh distributed magnitude, and with power decaying exponentially. A detailed description of the model can be found in [3]. Fig. 5 shows two typical channel snapshots with a channel delay spread of 100ns drawn from this model which we have used to evaluate the performance. These channel snapshots represent typical indoor office environments.

Fig. 6 shows the BER behavior of the UW-OFDM systems in comparison to the IEEE 802.11a system for channel A in
for \( N_r = 16, 20 \) and 24, respectively. We clearly notice that increasing the redundancy part, i.e. increasing \( N_r \), leads to a gain in the BER on one hand, but also leads to a decrease of the data rate on the other hand. As such, varying \( N_r \) has the effect of varying the (inner) coding rate of the system. Fig. 7 shows the results for channel B of Fig. 5. Even though the gains have reduced, we notice similar tendencies. We gain 0.9dB, 1.25dB and 1.75dB in case of \( r = 1 \) for \( N_r = 16, 20, 24 \). For \( r = \frac{3}{4} \), we gain 0.7dB, 0.8dB and 1.3dB, and in case of \( r = \frac{1}{2} \) 0.3dB, 0.8dB and 1.1dB, respectively.

Fig. 7. BER comparison between the novel UW-OFDM approach and the IEEE 802.11a system always outperforms the UW-OFDM approach.

- An increase of the number \( N_r \) of redundant subcarriers and thus a decrease of \( E_{b}/N_0 \) enhances the BER behavior of an UW-OFDM system. This effect can be interpreted as changing the inner coding rate of the system.
- The Wiener smoothing filter additionally improves the BER behavior. Dependent on \( N_r \), the UW-OFDM system may even outperform the IEEE 802.11a system.
- For the investigated frequency-selective scenarios, the UW-OFDM approach always outperforms the IEEE 802.11a system. The specific gain in performance depends on the outer coding rate \( r \), but also on the inner coding rate determined by the number \( N_r \) of redundant subcarriers.

V. CONCLUSION

In this work we demonstrated the relationship between the energy spent for the redundant subcarrier symbols in the frequency domain necessary to create the desired unique word in the time domain, and the BER behavior of such an UW-OFDM system. We showed that by increasing the number of redundant subcarrier symbols, which can be interpreted as changing the inner coding rate of the UW-OFDM system, and by choosing an appropriate distribution of them in the spectrum, the total energy of the redundant subcarrier symbols can be decreased and thus the BER behavior significantly improved. These results have been confirmed for the AWGN case as well as for typical frequency-selective indoor scenarios.
